ABSTRACT

We retrospectively evaluated the use of a suture-button technique to stabilize the plantar plate and lesser metatarsophalangeal joint (MTPJ) to alleviate pain and dysfunction due to failed digital surgery with lesser MTPJ dysfunction. Eight consecutive patients (8 feet, 13 rays) were studied, including 2 males (25%) and 6 females (75%). Their median age was 56.5 (range 25 to 72) years, and the median follow-up duration was 28 (range 21 to 36) months. Of the 8 patients, 7 (87.5%) underwent concomitant adjacent procedures. A 10-increment (equal intervals) pain score and the Bristol foot score (BFS) were used to assess subjective satisfaction and foot-related quality of life before and after surgery. The median preoperative pain score was 8 (range 5 to 10). Postoperatively, the median pain score was 0 (range 0), and the difference was statistically significant (p = .0106). The median preoperative and postoperative BFS was 53 (range 32 to 70) and 20 (range 18 to 34), respectively. The difference was also statistically significant (p = .018). One patient (12.5% of patients, 7.7% of rays) experienced wound dehiscence. All the patients indicated they would undergo the procedure again. From these findings, we believe the described suture-button technique is a useful method to stabilize the plantar plate and MTPJ after failed digital surgery.

was advocated by Jolly (26). Jolly promoted the use of small soft tissue anchors to repair the lateral collateral ligament, with release of the medial collateral ligaments, as adjunctive repair in crossover toe deformity. Over time, the combined use of internal fixation, specialized soft tissue anchors and suture materials and purpose-built instrumentation aimed at lesser MTPJ repair became popular. Thus, what seemed to many surgeons to be straightforward lesser MTPJ and plantar plate surgery entered the realm of high technology and relatively expensive specialized instrumentation and implants.

Chronic lesser MTPJ wear and tear and failed lesser toe surgery or trauma can lead to plantar plate attenuation or rupture. Patients with this condition will commonly present with lesser MTPJ instability and toe misalignment in the sagittal, transverse, and frontal planes. In addition, patients can develop degenerative joint disease of the lesser MTPJ, chronic MTPJ, and digital edema, hammer toe, or other interphalangeal contracture. Also, in many cases, a painful plantar keratosis will develop at the level of the metatarsal head, all of these factors contribute to lesser metatarsalgia (Fig. 1). The etiology of plantar plate disruption can be divided into 2 basic groups: patients in whom lesser digital surgery has failed; and patients with MTPJ predislocation syndrome (PDS). In cases of failed digital surgery, it could be that pre-existing plantar plate dysfunction was overlooked, resulting in a poor functional outcome with continued pain. Such patients often report an unsatisfactory outcome after traditional PIPJ fusion or arthroplasty with or without temporary MTPJ transfixation using a Kirschner wire (K-wire).

Just as with many painful musculoskeletal conditions, failure of the condition to satisfactorily respond to nonoperative treatments often results in surgical intervention. In the present report, we have described a series of 8 consecutive patients who experienced chronic forefoot pain subsequent to lesser MTPJ subluxation and/or failed digital surgery. All 8 patients underwent shortening metatarsal osteotomy, combined with a suture-button technique, to stabilize the involved lesser MTPJ. The aim of the present analysis was to determine whether the suture-button technique, combined with osteotomy, could provide satisfactory pain relief for these conditions and to provide preliminary outcome measures related to this technique. To the best of our knowledge, no previous studies have reported on metatarsal shortening osteotomy combined with the MTPJ suture-button method described in our report.

Patients and Methods

In this prospective case series, each patient presented to the senior author (M.S.J.) for consultation regarding chronic intractable forefoot pain due to chronic MTPJ subluxation and/or failed previous digital surgery. On presentation, the patients were considered for inclusion in the present study and informed of the investigation. After the patients had provided informed consent, the pertinent data were collected. Only patients who had presented with chronic forefoot pain associated with subluxation of the MTPJ, recalcitrant to conservative therapy, and after previous digital surgery, were considered for the present review. These patients were identified and enrolled in the series consecutively and were followed up as a group thereafter. To be included, the patients had to have experience intractable pain in the forefoot, with swelling and the inability to satisfactorily load bear on the symptomatic MTPJ. In addition, the patients had to display antalgic favoring of the painful foot as a consequence of the intractable pain and swelling. Moreover, to be included, the patients had to have reported that they could not continue their usual daily activities because of their foot pain. Still further, conservative treatment efforts, including the use of metatarsal sling pads and prescription orthotic devices, had to have failed. A total of 11 patients were identified as potentially eligible when they presented; however, 3 patients (27.3%) were excluded because they had had the following exclusion criteria. Of these 3 patients, 1 (33%) had diabetes mellitus and was involved in a litigation claim related to the previous digital surgery, 1 (33%) displayed peripheral neuropathy (33%), and 1 (33%) could not complete the foot-related quality of life questionnaire owing to cognitive impairment.
Suture-Button Stabilization of the Plantar Plate

The patient was positioned supine with the limb internally rotated for the best exposure. Hemostasis was achieved by anatomic dissection; no tourniquet was used. The target MTPJ was exposed using a dorsal approach. A sequential reduction began proximally at the MTPJ, with longitudinal release of the extensor expansion along the same side as the digital deviation (i.e., when the toe deviated medially, the longitudinal incision was made medial to the EDL tendon). A defect noted within the dorsal distal capsule was considered evidence of herniation of the metatarsal head in cases of severe instability. In the case of PDS, inspection of the joint capsule failed to reveal an osteochondral defect. Rather, capsular thinning and digital deviation at the MTPJ level were observed. In some cases, the lateral aspect of the metatarsal head was hypertrophic, similar to the eminence seen in a bunion deformity. In digits that had been deformed at the MTPJ for years, release of the plantar plate was performed using an appropriately sized McGlamry metatarsal elevator. A Weil osteotomy (27,28) was then performed in all cases, after which the metatarsal head was retracted to allow visualization of the floor of the joint. The capsule–plantar plate complex looked similar to the superior surface of the sesamoid apparatus present at the first MTPJ. For medially deviated digits, the joint was incised and the metatarsal head retracted laterally to expose the superior surface of the plantar joint capsule, which was visualized superficial to the plantar plate (Fig. 2). Both of these structures, the inferior joint capsule and the plantar plate, were observed to be confluent with the deep transverse intermetatarsal ligament (DTIL) and the flexor tendons. This composite of the lesser MTPJ fibrous capsule, plantar plate, DTIL, and flexor tendons are, in essence, the equivalent of the sesamoid apparatus of the first MTPJ. Typically, this complex will be the same color as tendon, appear smooth with a slight concave depression, and be rubbery in texture. However, when chronic degenerative changes were present, the coloration was yellowish or “tea-stained,” with evidence of hemorrhagic infiltrate not unlike that seen in chronic tendinopathy. In cases of lesser MTPJ floor chronic degeneration, attenuation of the plantar structures was present, rather than an overtly torn or ruptured plantar plate. Manipulation of the DTIL further exposed the plantar plate, pulling it from beneath the metatarsal, allowing for closer scrutiny of the complex (Fig. 2). At this point, the size, shape, texture, position, and alignment of the plantar plate were assessed. Definitive fixation of the osteotomy was completed using two 2.0-mm polydioxanone absorbable pins, typically 12 mm each (Fig. 2).

At this point, the tension in the EDL was assessed to determine that it rested under physiologic tension with the MTPJ and PIPJ in neutral position, after which the joint was stabilized using an absorbable suture-button technique. Physiologic tension is that tension that the MTPJ held in a neutral position. Specifically, a single strand of 3-0 undyed Vicryl® (polyglactin 910; Ethicon, Inc., a division of Johnson & Johnson, Somerville, NJ) was loaded onto 2 Keith needles and, with the foot and ankle held in a neutral position, the MTPJ held in a congruous position, and the corresponding digit held in a neutral to slightly plantarflexed position, depending on the severity of the deformity, the suture was used to stabilize the plantar plate. The suture was run from the capsular tissues at the dorsomedial and dorsolateral aspects of the metatarsal neck inferiorly into the floor of the joint capsule and plantar plate to harness the metatarsal neck in position (Fig. 3). The absorbable suture was positioned such that it would harness the neck of the metatarsal and the base of the phalanx (Fig. 4). The Freer elevator in the upper left corner undermines the capsule–plantar plate–DTIL complex beneath the MTPJ. At the level of the metatarsal neck, passing dorsally to the bones, 4-0 Vicryl® suture (Ethicon, Inc.) was placed distally and 2-0 Vicryl® suture was placed proximally (Fig. 4). The target Keith needle penetration in the region of the plantar plate is shown in Fig. 3D. Hemostats were used to pull the suture through the plantar fat pad, and a similar process was performed for the base of the proximal phalanx, running the suture inferiorly and proximally to pierce the capsule and plantar plate (Fig. 5). Once the suture was run out of the plantar fat pad of the forefoot, the sutures were attached to a sterile button and secured, holding the joint in a neutral position and with physiologic tension to maintain the digit stable in all 3 cardinal planes (Fig. 5). Because a digit that has been severely contracted for many years can be associated with a soft tissue sleeve and neurovascular structures that could be intolerant to complete reduction of the deformity (as evidenced by excessive skin tension or blanching of the tissues, suggesting vasoconstriction) the surgeon should be cognizant of the soft tissue tension during reduction of the deformity. The suture tension should be decreased in the event of excessive soft tissue tension to prevent neurovascular compromise. Finally, we interposed a drain sponge between the plantar skin and the sterile button to prevent cutaneous compromise. Numerous manual ties were performed to anchor the suture down across the sterile button onto the drain sponge. With the foot at 90° to the leg, the forefoot was placed in the neutral position, and capillary refill to the digital pulp was confirmed before applying the dressing. After administration of a supplemental local anesthetic injection for postoperative anesthesia, a sterile dressing was applied, followed by application of a modified compression dressing.

The postoperative protocol included the use of a modified compression dressing and a cryotherapy unit protected in a heel wedge shoe for 2 weeks. When the incision site had sufficiently coated, a compressive stocking and heel wedge shoe were continued for a minimum of 6 weeks postoperatively or when the suture–buttons had broken free, typically at 6 to 7 weeks postoperatively. Often, the adjunctive procedures (e.g., metatarsal osteotomy or first MTPJ arthrodesis) dictated when a patient should return to full weightbearing. Once the buttons had been removed, a metatarsal sling pad was used for all weightbearing activities in a firm-soled shoe. Before the patients had undergone surgery, all had been instructed that the use of a metatarsal sling pad would be required for the affected digits as preventative therapy for a lifetime.

Outcomes of Interest

The patients were followed up throughout their postoperative course, monitored for complications, and asked if they would undergo the procedure again to treat the same condition. Moreover, before and after surgery, each patient indicated their pain level using a 10-increment pain scale (29). Also, their foot-related quality of life was assessed using the Bristol Foot Score (BFS) (30). Weightbearing plain radiographs were also taken in the anteroposterior, medial–oblique, lateral, and forefoot axial views of the involved foot. Before the intervention, the patients were advised that the purpose of the surgery was to enhance joint stability in the hope of providing pain relief. As the investigation progressed, the senior author (M.S.J.) abstracted the data from the medical records, performed the surgical intervention, assessed the patients’ outcomes, analyzed the data, and collaborated with the coauthor (G.H.) to write the report.

Statistical Analysis

Statistically, we considered the data in terms of type and distribution and have described our series of patients in statistical terms. We also used nonparametric null hypothesis tests to compare the preoperative and postoperative outcomes of interest. Furthermore, we stratified the outcomes of interest into groups representative of 30% and 40% improvement. Statistical significance was defined at the 5% (p < .05) level.

Results

The suture-button technique was performed on 13 lesser MTPJs in 8 patients. The surgical procedures were performed between June
2010 and September 2011 (15 months). A statistical description of the series of patients is presented in Table 1 and the outcomes in Tables 2 and 3. The present case series included 8 patients (6 females [75%] and 2 males [25%]). Their median age was 56.5 (range 25 to 72) years. Of these patients, their median body mass index was 27 (range 23 to 31) kg/m², and the median follow-up duration was 28 (range 21 to 36) months.

Of the 8 patients, 5 (62.5%) had a single lesser MTPJ affected, including 4 second MTPJs (50.0%) and 1 fourth MTPJ (12.5%). These 5 patients were all female; 1 (12.5%) had moderate HAV and 1 (12.5%) had severe hallux varus. In 6 digits (46.2%), the lesser MTPJ floor appeared chronically degenerated with attenuation of the plantar structures, rather than appearing overtly torn or ruptured, as viewed at surgical dissection. None of the patients in the present case series displayed frank rupture of the plantar plate. The capsuloligamentous complex of the fourth MTPJ of 1 of the patients is shown in Fig. 2. The floor of the joint was exposed to reveal the capsule, plantar plate, and DTIL. However, all the patients had significant derangement in the plantar fat pad of the forefoot, ranging from inflammation with diffuse keratosis to very well-localized inflamed bursae and hardened keratoma formations plantar to the affected MTPJs. In each of these cases, moreover, the metatarsal parabola was defective, and decompression using metatarsal osteotomy was deemed necessary.

Of the 8 patients in our series, 6 (75%) reported that they had experienced complications due to failed forefoot surgery performed elsewhere. In 1 male patient (12.5% of 8 patients), lesser MTPJ arthroplasties had resulted in dorsal contractures at MTPJs 2 to 4 and dislocation of the third MTPJ with corresponding semiflexible hammertoe contractures in PIPJs 2 to 4. In another male patient (12.5% of total), failed digital arthroplasties had resulted in increased interdigital splay between the second and third digits associated with severe, semiflexible MTPJ contractures in the right foot (Fig. 6A). The chronic inflammation from this imbalance was evident in the plantar fat pads beneath MTPJs 2 and 3 (Fig. 6B). After recovery from surgery,
this patient was able to resume his usual weightbearing function, including loading the ball of the foot to raise his heel (Fig. 6C), and the chronic inflammation and keratosis he had experienced had resolved within 4 weeks postoperatively (Fig. 6D). Restoration of flexor digitorum longus (FDL) strength was also observed. The third patient, a female (12.5% of whole group), had experienced chronic pain from failed digital arthroplasties and first metatarsal osteotomy associated with flail toes and severe HAV deformity (Fig. 1). In this patient, the special risks of revisional digital surgery were discussed before the surgery. Before undergoing our procedure, she had had atrophic skin and subcutaneous structures and substantial contractures of soft tissue and tendons, which compounded the complexity of her case. The heightened risk of dysvascularity and wound complications and the potential need for amputation of the digit were all discussed in detail with the patient. In another female patient (12.5%), an attempt at soft tissue correction for hallux varus associated with second toe contracture failed to reduce the pain or deformity. A third female patient (12.5%) had experienced trauma to the second digit and, despite open reduction and internal fixation and continued to have swelling, pain, PIPJ malunion, and stiffness. The fourth female patient (12.5%) experienced continued subsecond MTPJ pain despite first metatarsal osteotomy and second toe arthroplasty. Finally, 2 of the 8 patients (25%) had developed MTPJ deformity and dysfunction without having undergone previous surgery. Of the latter 2 patients, 1 (12.5% of total group) had developed posttraumatic pain and instability owing to an untreated digital fracture. In the second patient (12.5%), the MTPJ

deformity and dysfunction had resulted from recalcitrant PDS secondary to flexor instability. All the patients reported that they could not tolerate walking barefoot, with significant disruption of their activities of daily living preoperatively.

Six types of adjunctive procedures were performed with the suture-button technique. These included 13 lesser metatarsal osteotomies (8 second [61.5%], 3 third [23.1%], and 2 fourth [15.4%]), 1 first metatarsal osteotomy (12.5%), 2 first MTP arthrodeses (25%), 4 PIP arthrodeses (31.1%), 3 second digit interphalangeal exostectomies (23.1%), 1 third digit interphalangeal exostectomy (7.7% of rays), 1 hallux interphalangeal exostectomy (7.7% of rays), and 1 Akin osteotomy (12.5% of patients).

Using the incremental pain scale (Table 2), the median preoperative score was 8 (range 5 to 10), and the final postoperative score was 0. This difference was statistically significant ($p = .0106$). All 8 patients (100%) experienced at least a 40% decrease in pain (Table 3). Using the BFS (Table 2), the median preoperative score was 53 (range 32 to 70). The final BFS score was 20 (range of 18 to 34). This difference was also statistically significant ($p = .018$). Of the 8 patients, 7 (87.5%) experienced ≥30% improvement in their BFS, and 6 (75%) experienced ≥40% improvement in their BFS (Table 3). Furthermore, 1 patient (12.5% of patients; 7.7% of rays) experienced wound dehiscence, which healed with local wound care. Also, all the patients indicated they would undergo the procedure again for the same condition.

Discussion

The present report serves as an extension of the work by Gerard V. Yu, DPM (deceased) in addressing the chronic and debilitating pain syndrome that can accompany lesser MTPJ instability most accurately described as PDS (31,32). In PDS, weakness and instability result in imbalance of the MTPJ. When the second MTPJ is involved, the principle structures that become weakened include the second dorsal

interosseous muscle, FDL, plantar plate, and first lumbral, resulting in sagittal and transverse plane instability of the MTPJ. Specifically, weakness in each of these structures in the second ray contributes to slow, progressive elevation at the MTPJ (weakened first lumbral), medial subluxation of the toe (weakness of the second dorsal interosseous), mild and reducible flexion contracture at the PIPJ, and plantar pain beneath the base of the digit (weakness of the FDL and chronic inflammation of the plantar plate). In our experience, conservative therapy can often provide sufficient comfort and adequate return to function, thereby obviating the need for surgery for many patients. However, for the subset of patients in whom conservative therapy fails, chronic forefoot pain due to plantar plate insufficiency, edema, degenerative joint disease of the lesser MTPJ, and painful plantar keratosis formation are among the conditions that lead to severe disability and intractable pain at the base of a digit and within the ball of the foot. Metatarsalgia due to PDS and complications from failed digital surgery accounted for the disability and chronic forefoot pain in the patients described in the present case series. In these patients, the physical disability and emotional upheaval from the chronic pain had become unbearable. In some patients, the disability interfered with gainful employment, reduced their ability to cope with daily activities, interfered with their sleep–wake cycle, and was mood altering, affecting their entire family. In our experience, the condition of these patients is often misdiagnosed as a neuroma or simple hammertoe deformity, and other patients are misconstrued as malingering. When lesser MTPJ dysfunction has been misdiagnosed, surgery can fail to stabilize the MTPJ, resulting in recalcitrant or worsened pain.

In more traditional hammertoe surgery, when release of the plantar MTPJ is required, K-wire stabilization (transfixation) of the joint has been commonly used. Although such pinning has been shown to stabilize the joint and prevent recurrence of deformity in the short term (33), no long-term radiographic or clinical analyses have ever been reported, to the best of our knowledge. To effectively stabilize the MTPJ, a K-wire can be retrogradely across the joint and seated in the cancellous bone of the metatarsal base to prevent premature loosening and extrusion of the pin. This retrograde pinning of the digit is tedious and can require >1 attempt to achieve neutral joint alignment. Using a 0.062-in. K-wire to transfixate the joint often results in more than one 1.6-mm hole in the subchondral bone plate and joint cartilage (34). Given that the metatarsal head contact area is small, repeated attempts at pinning across the joint could damage the articular surfaces. Although the clinical significance of this has yet to be determined, we suspect that repeated punctures through the cartilage could invoke degenerate changes, and prolonged K-wire fixation of the lesser MTPJ could result in persistent joint stiffness, which could complicate recovery and reduce long-term satisfaction. It is important to understand that instability of the MTPJ–plantar plate complex can exist independently of hammertoe contracture. Also, these deformities can be separate and distinct clinical entities (e.g., PDS). The potential complications of digital arthroplasty and arthrodesis can often be avoided once the MTPJ–plantar plate complex has been stabilized. Because arthroplasty and arthrodesis of the digit includes dissection of the digital soft tissues, lymphatic and other small caliber neurovascular structures will be manipulated and can potentially be injured, resulting in chronic edema that can be very difficult, if not impossible, to reduce in some patients. Alternatively, decompression of the MTPJ, whether from simple release of the MTPJ or shortening of the metatarsal segment, will result in relaxation or functional lengthening of the long tendons, with subsequent reduction of flexible digital contractures. This virtual lengthening of the tendons could obviate the need for digital arthroplasty or arthrodesis. The suture-button technique we have described could then be used as an adjunct procedure to secure the plantar plate and stabilize the floor of the joint to secure the plantar plate to the underlying joint capsule while the tissues heal over time.

When the length pattern of the ray is the primary deformity, metatarsal osteotomy can often be beneficial (18–21,23,24). A variation on that theme is en bloc bone resection from the metatarsal neck and shaft, stabilized with a 1/4-in. tubular plate and screws (21). Alternatively, others have proposed that direct repair of the plantar plate is necessary to restore balance and function about the digit (18). In 1 technique described by Weil et al (24), the plantar plate was sutured with a stitch run through a bone tunnel within the proximal phalanx to stabilize the plate relative to the bone. Weil et al (24) documented good results for numerous patients, although their technique required tunneling of the small cortical margins of the proximal phalanx and completely detached the plantar plate before its repair. We believe the suture-button technique we have described has distinct advantages in that it does not detach the plantar plate and it uses absorbable suture to secure the complex. Moreover, bone tunnels are not needed; therefore, the technique avoids the complications that could accompany bone work (understanding that a Weil osteotomy was used with the suture-button). Another advantage of the suture-button technique is that it can avoid the need to open the digital sleeve and deglove the digit altogether, because most of the incision spans the metatarsal neck and terminates at the base of the proximal phalanx. Hence, in many cases, it will not be necessary to violate the bone at the digital base or interphalangeal joint. Collectively, these advantages reduce the complexity of the procedure, reduce the risk of bone complications in the digit, and eliminate violation of the digital sleeve and articular surfaces, which can result in longstanding edema, neuritis, and stiffness.

The suture-button technique we have described is essentially a culmination of the ideas explored by others during the past 8 decades. Our technique can be most likened to the Lambrinuidi external digital split described in the report by Taylor (4), in which suture was used to anchor the proximal phalanx, with the suture run out the sole of the foot and postoperative shoe. Cicchinielli (35) has also thoroughly discussed the concept of addressing digital pathology at the level of the MTPJ as the primary procedure to reverse digital contracture. Also, it was a personal communication with Cicchinielli that led to the development of our described technique. The concept of harnessing the proximal phalanx base and anchoring it in position can be traced back in published reports to as early as 1925 (10) and has been the focus of subsequent procedures geared at stabilizing the second digit. The earliest reported procedure described an FDL tendon transfer to the proximal phalanx (2). However, the concept of plantar plate stabilization or repair was not considered at that time. In the present case series, the Girdleston method (36) of harnessing the proximal phalanx was simulated and taken a step further by also harnessing the metatarsal neck to stabilize both the phalanx base and the metatarsal head to the plantar plate and underlying soft tissue bed. The procedure we espoused anchors the plantar plate in place using absorbable suture strands that course out of the foot through the plantar fat pad of the forefoot. No special equipment is needed for this procedure; thus, the technique is relatively inexpensive in terms of the materials needed to complete the maneuver. The procedure requires only Keith needles, a sterile button, and absorbable suture. Just as with all surgical interventions, the mere cost of the materials used in the operation is only 1 facet of cost-effectiveness, and a thorough cost-effectiveness analysis, complete with a definition of quality-adjusted life-years, is required to define the cost-effectiveness of this technique compared with any other.

The suture-button technique we have described also proved effective in complicated cases with failure of previous forefoot surgery. It was important to have the patients demonstrate their ability (or inability) to rise up on their toes (heel raise) and to actively hold their toes against the ground in the preoperative examination, allowing for a clear understanding of their baseline function. The goal, especially
in the cases of failed digital surgery, was pain relief, with was no guarantees regarding a change in toe function or cosmesis. We believe this approach was prudent, because some of the toes had not been able to grip the ground for years. Using the suture-button procedure, combined with the Weil osteotomy, the long tendon function to the toe was maintained if normal grip strength was evident before surgery. Using the “paper pull out test,” the patient shown in Fig. 6E was able to grip a piece of paper and resists its pull out postoperatively. Also, in the same patient, plain radiographs had revealed interdigital splay to grip a piece of paper and resists its pull out postoperatively. Also, in the same patient, plain radiographs showed improved joint congruity after surgery (Fig. 7A); however, the postoperative radiographs showed improved joint congruity after stabilization using our technique (Fig. 7B).

In all cases in our series, Weil osteotomy was performed as described previously (19,27,37,38). Also, we stabilized the osteotomy using dual absorbable pins. The osteotomy functionally changes the axis of motion, similar to that noted with decompression osteotomy for hallux limitus.

Inspection of the MTPJ joint cartilage was always performed. However, in the cases of PDS, no gross osteochondral defect was ever identified. Similar to the findings in hallux abductovalgus deformity, the articular cartilage of the lesser metatarsal was typically intact and healthy appearing. The exception in our series included 3 patients (37.5%) whose joints were complicated by previous arthrodesis or arthroplasty. In the 8 digits (61.5%) of these 3 patients, cartilage degeneration and hypertrophic degenerative changes of the metatarsal head were evident years after the index procedures of PIPJ arthrodesis and MTPJ pinning. In 1 patient (12.5%), >8 years of semirigid and rigid joint contractures had resulted in these degenerative changes of the lesser MTPJs. In such cases, we believe that release of the plantar plate is required owing to the presence of longstanding adhesion formation. In the present case series, ≤3 years of radiographic follow-up confirmed bone and joint stability. Moreover, in our experience to date, we have not had to perform direct open repair of the plantar plate.

Regarding revision of PIPJ arthrodesis, we performed this in 4 toes (30.1%). In each case, we did not transfixate the MTPJ with a K-wire. By using absorbable suture, the inflammatory reaction about the joint was relatively short lived, and, because absorbable suture is not stiff, it will not physically irritate the adjacent tissues, in contrast to non-absorbable materials. One case of wound dehiscence (12.5%) developed in a patient who, incidentally, was an active tobacco user; however, our analyses did not enable us to elucidate the precise association of any exposure to this complication.

The exclusion criteria in the present study were used to eliminate variables that could interfere with evaluation of the patients and their subjective input. Joint dysfunction due to hyperglycemia and generalized glycosylation of tissues throughout the forefoot, joint derangement due to neuropathic joint injury, legal issues, or a patient’s inability to participate in the preoperative and postoperative interviews were considered major variables that could likely skew the data. Therefore, the patients with diabetes, peripheral neuropathy of any etiology, an active worker’s compensation case, and cognitive disability were not included.

Using the suture-button technique we have described has been very rewarding to date, both for us as surgeons and for our patients. This suture-button technique for stabilization of the lesser MTPJ is distinctive in that it does not disrupt the flexor tendons or the plantar plate, in contrast to direct open repair. It uses absorbable suture to anchor the bone against the plantar plate, resulting in stabilization of the entire MTPJ complex. In essence, we believe this provides physiologic restoration of joint congruity and positioning of the joint over the plantar plate, which, in turn, enables the long tendons to regain their mechanical advantage across the MTPJs. This functional lengthening of the tendons often allows avoidance of osseous procedures commonly performed at the PIPJ level, although metatarsal osteotomy seems to be necessary to address misalignment of the metatarsus. A further benefit of this method, compared with K-wire transfixation is that an external K-wire is not maintained at the tip of the digit during the early postoperative phase, a known subjective preference of patients. Still further, our suture-button procedure is technically simple and likely to be cost-effective.

One important weakness of our study was that a single surgeon performed the clinical and radiographic evaluations and all the operations, which could have imparted the biases inherent whenever surgeons analyze their own work. Another weakness was the small size of the case series. We recognize that well-designed cohort studies and randomized controlled trials are required to validate our clinical outcomes. Nonetheless, we believe that the present findings can be used in the development of more rigorous and less-biased clinical investigations. Since the time this article was submitted, 6 of the 8
patients in this study remain in the senior author’s practice. Each would have their procedure preformed again if necessary.

In conclusion, we believe that the success of the presented suture-button technique, performed in conjunction with metatarsal osteotomy, results from the enhanced stability of the complex structure composed of the plantar plate, ligaments, and joint capsule of the MTPJ. In the present group of patients, the technique was used to successfully stabilize the lesser MTPJ, eliminate pain, improve function, and impart substantial subjective patient satisfaction.

Acknowledgments

In memory of Dr. Gerard V. Yu, whose zest for life and insatiable intrigue for details have made a true difference for foot and ankle surgeons worldwide. A deep debt of gratitude to Dr. Scot Malay for his expertise in statistical analysis and depth of knowledge for the pathology studied herein. Special thanks also for the efforts of the medical library staff at the Health Science Library, Mercy St. Vincent Medical Center of Toledo, Ohio, for their assistance in research and acquisition of studies required for our report.
